Which policy-mix to mitigate the effects of financial heterogeneity in a monetary union?

Cristina Badarau* and Grégory Levieuge♣

Abstract

This paper aims to study a suitable policy-mix for a monetary union like the euro area, in a context of financial heterogeneity. It relies on a DSGE model with empirically-justified heterogeneous bank capital channel, with financial shocks, in addition to monetary, budgetary and technological ones. The analysis leads to the following conclusions. A centralized monetary policy appears to be more advantageous for the union than an alternative inflation-divergences oriented policy. Besides, national budgetary policies can mitigate cyclical divergences. Nevertheless, the exam of various policy-mixes indicates that the superiority of a cooperative budgetary regime only relies on the fact that it allows a better stabilization of public spending divergences in the Union. On the other hand, national variables are less stabilized under this regime. These results are finally discussed in light of the subprime mortgage crisis context.

Key words: euro area, financial heterogeneity, monetary/budgetary policy rules, DSGE model.

JEL classification: E44, E58, E63, C61

1 Introduction

The European Monetary Union members have not been identically affected by the subprime mortgage crisis, whose origin was however a common financial shock. In this respect, this crisis reasserts the structural heterogeneity of the EMU1. More precisely, recent studies2 indicate that the European financial system in particular remains far from being integrated. The banking markets precisely appear as the most heterogeneous financing market; price differentials remain high compared to other monetary unions, and home biases in lending to and borrowing of

1 The heterogeneity of the EMU is analyzed in detail in Jondeau & Sahuc (2008), Sekkat & Malek Mansour (2005), Angeloni & Ehrmann (2007), Ekinci & al. (2007), Hofmann & Remsperger (2005), and Lane (2006).

small non-financial corporations and households are persistent. Credit conditions thus depend on national firms’ and banks’ financial structures.

Next, the subprime mortgage crisis also demonstrated that banks constitute key actors for the transmission of financial shocks. In that sense, several recent contributions have highlighted the importance of the bank capital channel, according to which, through the adjustments of their balance sheet structures, banks act as amplifiers for the transmission of shocks to the real economy. Following this literature, the question of banks’ financing is as problematic as the question of external financing for firms. Because of an agency problem between banks and their creditors, the former bears an external financial premium which is negatively related to their capital ratio (and so is counter-cyclical). This external financing premium is ultimately passed on to the credit conditions to firms.

Considering simultaneously the main factors underlying the bank capital channel, a preliminary empirical study by Badarau-Semenescu & Levieuge (2010a) indicates that European countries are ought to be more (Germany, Italy, Netherland) or less (Finland, France, Spain) sensitive to this mechanism. So this channel constitutes an interesting way to model the effects of the financial heterogeneity in the euro area. In this perspective, Badarau & Levieuge (2010b) provide a DSGE model of financially-asymmetric monetary union and show 1) how symmetric shocks produce cyclical divergences inside the union, and 2) that a common monetary policy worsens cyclical divergences in this context.

So, given the role of banks in propagating shocks (namely financial which have become recurrent in the last decades), the heterogeneity of banking markets raises the question of the appropriate macroeconomic policies in such a context. Certainly, avoiding huge financial crisis requires adequate micro and macro-prudential measures (Levieuge, 2009). The reduction of financial heterogeneity also demands a convergence of structural policies. But both need time and strength of will to be implemented. It is thus worth examining the suitable mixing of the two main existing EMU policy tools: the common monetary policy led by an independent Central Bank and the budgetary policies conducted by national governments. Since 2008, intensive debates have concerned the lack of coordination of economic stimulus plans inside the euro area, and the way the EMU-members could help the most affected countries. Discussions also exist

---

3 According to Angeloni & al. (2003), the asymmetric information between lenders and borrowers in the European credit markets could partly explain these price differentials.

about the appropriate design of monetary policy. The aim of the present article is to study some policy-mix arrangements likely to mitigate the effects of financial asymmetries in a monetary union possibly hit by financial shocks.

To this end, we proceed to some policy experiments based on the Dynamic Stochastic General Equilibrium (DSGE) model provided by Badarau & Levieuge (2010b), for a monetary union gathering two countries with distinct banking structures and national budgetary policies. The present paper differs from the existing literature as it considers: (i) a bank capital channel, (ii) financial heterogeneity, (iii) financial shocks and, (iv) the evaluation of various policy-mixes, in the institutional context depicted by the Treaty of Lisbon.

It is found that a centralized monetary policy, seeking to stabilize the union-wide inflation rate, dominates a strategy that is simultaneously concerned by the stabilization of inflation divergences in the union. This is true whatever the budgetary regime (cooperative or non-cooperative), supporting the current orientation of the European Central Bank (ECB) policy for the euro area. Besides, national budgetary policies constitute relevant instruments (although insufficient) to fight the asymmetric transmission of shocks in a monetary union with financial heterogeneities. Nevertheless, the analysis of different policy-mixes shows that a cooperative regime is costly at national level. Its superiority only relies on the fact that it allows a better stabilization of public spending divergences.

The reminder of this paper is organized as follows. The second section resumes the baseline model with financial heterogeneity. The third section briefly discusses the role of the centralized monetary policy to amplify cyclical divergences in such an asymmetric union. The capacity of different macroeconomic policies to mitigate the effects of financial structural heterogeneity is then analyzed in the fourth section of the paper. The last section formulates some concluding remarks.

2 The baseline model

The model, based on Bernanke & al. (1999), describes a two-country monetary union with heterogeneous national banking structures. It is very close to the model recently provided by Badarau & Levieuge (2010b), with an extension considering the potential stabilizing role of

---

6 To this respect, the monetary policy tightening decided by ECB in summer 2008 for instance had been widely commented.

7 Previous examples of monetary policy analysis in two-country models with different financial systems are provided by Faia (2002) or Gilchrist & al. (2002). The last one is more close to our model, because it addresses the question of the monetary policy conduct in a monetary union. The authors settle for introducing asymmetric firms’ balance sheet channels within the union and analyze the transmission of technological shocks. We extend their study considering the effects of a bank capital channel and evaluating different policy-mix strategies in an asymmetric union.
national governments in a monetary union. The main structure of each member country is depicted in appendix A. Six categories of national agents optimize their decisions in the model: households, entrepreneurs, retailers, capital producers, banks and a government.

Households supply labour and own the retail firms. They receive wages from entrepreneurs and profits from retailers, and use them for consumption and savings. Because the model consists of a two-country monetary union, domestic households simultaneously consume domestic goods and goods produced in the other country of the union. They also pay lump-sum taxes to the Government, necessary to finance the public expenditures. Entrepreneurs (firms) use labor and capital as input (partially financed by debt) to produce wholesale final goods, in perfectly competitive markets. Retailers buy wholesale goods from the producers. They slightly differentiate them (with no costs) and retail them in a monopolistic competition market. CES aggregates of retail products are bought by households and also by capital producers, who transform retail goods in capital (used by the entrepreneurs, in the production process). The role of banks is twofold in the model: on one hand, they participate as lenders to the national firms investment projects. On the other hand, they collect funds from households, so as to insure the firms financing. The national banking sectors have a particular place in the model, being considered heterogeneous among countries.

At the union level, a common Central Bank is responsible for the conduct of the monetary policy. As for the euro area, the main task of the Central Bank is to maintain the price stability, while the national governments should insure the stability of national aggregates.

2.1 The general equilibrium

Each country is inhabited by a continuum of infinitely-lived households represented by the unit interval. These agents choose consumption \( C^i \) and leisure \( L^i \) and determine the working time \( H^i = 1 - L^i \) remunerated at a real rate \( W \). The one period utility function is given by:

\[
U(C^i, H^i) = \frac{\sigma_c}{\sigma_c - 1} C^i, \frac{\sigma_c - 1}{\sigma_c H^i + 1} \]

with \( \sigma_c \) the consumption intertemporal elasticity of substitution, and \( \sigma_h \) the elasticity of the disutility associated to labour.

Consumption is a composite index which depends on the consumption of goods domestically produced and goods produced in the other country of the union. The origin of goods is indexed by 1 and 2, while \( C^1 \) and \( C^2 \) denote aggregate consumption in the first and the second country of the union, respectively. \( \gamma \in [0,1] \) represents the relative preference for consumption of domestic produced goods, in each country.
\[ C = \frac{C_1^\gamma C_2^{1-\gamma}}{\gamma^\gamma (1-\gamma)^{1-\gamma}}; \quad C^* = \frac{(C_1^\gamma)^{1-\gamma} (C_2^{1-\gamma})^\gamma}{\gamma^\gamma (1-\gamma)^{1-\gamma}} \]  

(2)

Price indexes for the two countries are respectively: \( P = P_1^\gamma P_2^{1-\gamma} \) and \( P^* = P_2^\gamma P_1^{1-\gamma} \), and the law of one price is supposed to hold.

*Households* choose a sequence of consumption, labour, bank securities \((A_t)\) and other possible financial investment \((D_t)\) at the real risk-free interest rate, which maximizes an intertemporal utility function, based on (1), subject to the following budget constraint:

\[
P_tC_t + P_tD_t + A_t \leq P_t^tW_h + A_{t-1}R^A_t + P_tD_t, R^f_t - T_t + \Pi_t \]  

(3)

In (3), \( R^A_t = 1 + r^A_t \) and \( R^f_t = 1 + r^f_t \) denote respectively the gross real returns of the two alternative financial investments for households, \( T_t \) represents lump sum taxes and \( \Pi_t \) are the dividends received from the ownership of retail firms. Symmetric constraint applies in the second country of the union.

The first order conditions associated to \( C_t, D_t, A_t \) and \( H_t \) for the two countries appear in the table 1. At the optimum, there is no arbitrage for households among the different financial investments. The labor supply is given by the last condition in table 1, and the nominal interest rate is the same inside the union (chosen by the common central bank):

\[
(R^f_t)E_t \begin{bmatrix} P^t_{t+1} \\ P_t \end{bmatrix} = (R^*_{t+1})E_t \begin{bmatrix} P^*_{t+1} \\ P_t \end{bmatrix} .
\]

Under nonrestrictive assumptions similar to Gali & Monacelli (2009), this allows us to write:

\[
C_t = C_t^*(\Theta_t)^{\sigma_t} \]  

(4)

where \( \Theta_t = \frac{P_t^*}{P_t} \) is an expression of the bilateral terms of trade.

Wholesale producers combine labour and capital with a Cobb-Douglas constant return to scale technology:

\[ Y_t = a_t K^{\alpha} L^{1-\alpha} \] and \[ Y_t^* = a_t^* (K_t^*)^\alpha (L_t^*)^{1-\alpha} \]  (5)

with \( a_t \) an exogenous productivity factor that follows a standard autoregressive process in the model: \( a_t = \rho_a a_{t-1} + \varepsilon_a \), where \( \varepsilon_a \) defines a productivity shock, with zero mean and unit variance. The labour input in (5) is a composite index of households labour \( (H_t) \) and entrepreneurial labour \( (H_t^\xi) \): \( L_t = H_t^\alpha (H_t^\xi)^{1-\alpha} \). As indicated previously, entrepreneurs supplement their income by supplying their labour force, remunerated at a rate \( W_t^\xi \). Note that the total entrepreneurial labour is normalized to unity. In each country, the investment \( (I_t) \) is supposed to concern domestic produced goods. The accumulation of physical capital is introduced by the following equation, with \( \delta \) the depreciation rate:

\[ K_{t+1} = (1-\delta)K_t + I_t \]  (6)

It is also assumed that there are some internal capital adjustment costs \( \Phi(.) \) borne by the capital producers, who buy \( I_t \) units of final goods and transform them into physical capital with they afterwards sell to entrepreneurs.

\[ \Phi(I_t, K_t) = \frac{\phi}{2} \left( \frac{I_t}{K_t} - \delta \right)^2 K_t \text{, for } \phi > 0 \]  (7)

Noting \( \rho_t = \frac{P_t^w}{P_t^l} \), the relative price of wholesale goods produced in the country 1, \( Q_t \) the Lagrange multiplier associated to the process of capital accumulation, and given the term of trade \( \frac{P_t^1}{P_t^2} = \Theta_t \), the profit maximization program of domestic firms gives the first order conditions (relative to \( H_t, H_t^\xi, I_t \) and \( K_{t+1} \) respectively), reported in the table 2.

\(^{*} \) For the second country of the union the first order conditions are symmetric, except for the exponent of \( \Theta_t \), which becomes \( (\gamma - 1) \) instead of \( (1-\gamma) \).
As in Levieuge (2009) the profit maximization of capital producers is internalized in this program. The first two conditions define the labour demands. The third gives the Tobin’s Q ratio. The last relation represents the expected gross return to holding a unity of capital from \( t \) to \( t+1 \).

It is assumed that the debt contracts between households and banks on one hand, and between banks and firms in the other hand, occur in an asymmetric information context. Entrepreneurs have private information about the risk and the return of their projects, and banks have private information about the risk and the realized return of their activity. It is shown in Badarau & Levieuge (2010b) that, in these conditions, banks and firms have to bear a financial premium in their external financing. In these conditions, the last relation in table 2 indicates that, at the optimum, the firms’ demand for capital insures the equality between the expected marginal cost for the external financing and the expected marginal return on capital. The main relations which describe the financial market equilibrium for the member countries are depicted in table 3.

</tbody>
</table>

\(^{*}\) relations are identical for the second country of the union.

The external finance premium for banks, the logarithmic form of \( S_t^B \), is the difference between the non-default net return on the bank’s loans portfolio required by the household \( \left( r_{t+1}^B = R_{t+1}^B - 1 \right) \) and the risk-free interest rate \( \left( r_{t+1}^F = R_{t+1}^F - 1 \right) \). As described in the table 3, it only depends on the banks’ financial leverage, defined by the ratio accumulated inside capital \( \left( NB_t \right) \) on loans \( \left( B_t \right) \).

For firms, the external finance premium (the logarithmic form of \( S_t^F \)) is the difference between the net return on the firm’s physical capital required by the bank \( \left( r_{t+1}^K = R_{t+1}^K - 1 \right) \) and the risk-free rate \( \left( r_{t+1}^F = R_{t+1}^F - 1 \right) \). In table 3, it does not only depend on the firm’s accumulated net
wealth \((NF_i)\), but also on the accumulated inside capital of the bank \((NB_i)\). Thus, the lending interest rate required by a bad-capitalized bank is ought to be higher than that charged by a healthier one. This implies that entrepreneurs internalize the banks’ external financing costs. A deterioration of the banks’ balance sheet finally implies a tightening of the lending conditions to firms, which is precisely the bank capital channel manifestation.

The firm’s net worth \((NF_i)\) mainly comes from the accumulated benefits, i.d. the accumulated value of the firm \((VF_i)\). It is also assumed that the entrepreneur offers its labour force\(^8\) and perceives a wage \((WF_i)\), which increases the firm’s net wealth. The coefficient \(\gamma^F\) in table 3 corresponds to the survival probability of the firm, assuming that a constant proportion \((1 - \gamma^F)\) of firms leave the market each period. When living the market, the remaining net wealth is entirely used to consume final goods \((CF_i)\): 

\[
CF_i = (1 - \gamma^F) \left[ VF_i + WF_i \right] = \frac{1 - \gamma^F}{\gamma^F} NF_i.
\]

Besides, the value of the firm \((VF_i)\) is given by the gross return on capital, after the repayment of the debt and of the associated interests.

In a similar way, the bank inside capital \((NB_i)\) comes mainly from the accumulated benefits of the intermediation activity, i.d. the intrinsic value of the bank \((VB_i)\). Besides, it is assumed that a proportion \((1 - \gamma^B)\) of banks leaves the market each period, transferring a small part \((t^B)\) of their inside capital to new banks\(^9\) (for an aggregated amount \(T^B_i\)). The outgoing banks, once their transfers to newcomers done, consume in final goods their remaining capital:

\[
CB_i = (1 - \gamma^B)(1 - t^B)NB_i = \frac{(1 - \gamma^B)(1 - t^B)}{\gamma^B(1 - t^B) + t^B} NB_i.
\]

**Retailers** are represented by firms, held by households, which purchase wholesale goods and retail them afterwards. Their main role is to differentiate final goods. Following Calvo (1983), it is assumed that a retailer changes his price with probability \(1 - \varsigma\), in a given period. Subsequently, the retailer pricing behavior leads to the following ‘new Phillips curves’ in the two countries of the union:

\[
\dot{\pi}_{1,i} = \beta E_t[\dot{\pi}_{1,i+1}] + \kappa \hat{\pi}_i \quad \text{and} \quad \dot{\pi}_{2,i} = \beta E_t[\dot{\pi}_{2,i+1}] + \kappa \hat{\pi}_i^* \quad (8)
\]

where \(\pi_{1,i} = \log(P_{1,i} / P_{1,i-1})\) and \(\pi_{2,i} = \log(P_{2,i} / P_{2,i-1})\) give the inflation rates calculated in the

---

\(8\) This assumption just allows the wholesale producers to borrow immediately; otherwise, they should face an unrealistically high external finance premium.

\(9\) In line with other financial accelerator models, this assumption gives the possibility to new banks to benefit from initial capital, which is essential for the access to external financing. Without initial wealth, newcomers would suffer prohibitive external financial premium.
domestically priced goods for the two countries, \( \kappa = \frac{(1-\xi)(1-\xi\beta)}{\xi} \) and \( \rho_+, \rho_-^* \) are respectively the real marginal cost for a representative retailer in each country. \( \hat{x}_t \) defines, for all \( x_t \), the deviation of a variable \( x_t \) from its steady-state value.

The national goods and labour markets equilibrium conditions imply:

\[
Y_t = \Theta_i^{1-\gamma} C_i \left[ \gamma + (1-\gamma)(\Theta_i^{1-\sigma_i} - 1) \right] + I_t + G_t + CF_i + CB_i
\]

\[
Y_t^* = \left( \Theta_i^{1-\gamma} C_i \right)^{1-\sigma_i} \left[ \gamma + (1-\gamma)(\Theta_i^{1-\sigma_i} - 1) \right] + I_t^* + G_t^* + CF_i^* + CB_i^*
\]

and respectively:

\[
\left( H_t \right)^{\frac{\sigma_x+1}{\sigma_x}} = \left( C_i \right)^{\frac{1}{\sigma_x}} \rho_x (\Theta_i)^{1-\gamma} \Omega (1-\alpha) Y_t
\]

\[
\left( H_t^* \right)^{\frac{\sigma_x^*+1}{\sigma_x^*}} = \left( C_i^* \right)^{\frac{1}{\sigma_x^*}} \rho_x^* (\Theta_i)^{1-\gamma} \Omega (1-\alpha) Y_t^*
\]

National governments are responsible for the budgetary policy. They use lump-sum taxes to finance public expenditures. To insure the stability of national aggregates, governments use conventional active budgetary policy rules (see for instance Muscatelli & al. (2004)):

\[
\hat{g}_t = \rho_g \hat{g}_{t-1} + \rho_g \hat{\pi}_t + \rho_y \hat{y}_t + \varepsilon_{\hat{g}_t}
\]

\[
\hat{g}_t^* = \rho_g^* \hat{g}_{t-1}^* + \rho_g^* \hat{\pi}_t^* + \rho_y^* \hat{y}_t^* + \varepsilon_{\hat{g}_t}^*
\]

where \( \rho_g, \rho_g^* < 1 \), and \( \rho_y, \rho_y^* < 0 \) represent the reaction coefficients of the budgetary policy to national inflation deviation from the steady-state, \( \rho_y, \rho_y^* < 0 \) are the coefficients of reaction to the output-gap deviation from the steady-state. \( \varepsilon_{\hat{g}_t}, \varepsilon_{\hat{g}_t}^* \) are random shocks with zero mean and unit standard deviation.

Finally, the common Central Bank conducts the monetary policy following a standard monetary policy rule (with respect to the union-wide inflation):

\[
\hat{r}_t^n = \beta_0 \hat{r}_{t-1}^n + (1-\beta_0) \beta_i \hat{\pi}_t^{UM} + \varepsilon_{\hat{r}_t}
\]

where \( \hat{\pi}_t^{UM} = \frac{1}{2}(\hat{\pi}_t + \hat{\pi}_t^*) \). The \( \beta_i \geq 0 \) coefficient corresponds to the reaction of the monetary policy to the union-wide inflation deviation from its steady-state level. \( \beta_0 \in [0;1] \) is the smoothing
coefficient of the nominal interest rate. \( \varepsilon_q \) represents a monetary policy shock of zero average and standard deviation equal to 1.

In addition to technological, budgetary and monetary shocks that are introduced in equations (5), (11) and (12), financial shocks are also considered in the model. In previous equations, \( Q_t \) represents the fundamental value of the firms’ physical capital, given by the actualized amount of dividends to be obtained by the firms’ shareholders. We now allow for the possibility that the market value of the capital, denoted hereafter by \( Q^m_t \), differs temporarily from its fundamental value \( Q_t \), because of a temporary financial shocks \( \{ \varepsilon_q \} \):

\[
Q^m_t = Q_t + \varepsilon_q,
\]

with \( \varepsilon_q \) a random variable of zero average. If the shock arises in \( t \), it affects the market value \( Q^m_t \) of the capital only at this period; afterwards, starting from the \( t+1 \) period, the equality between \( Q^m_t \) and \( Q_t \) holds again. Hence, in case of financial shock, the fundamental return on the physical capital given in Table 2 becomes an abnormal return on capital given by:

\[
R_{t}^{km} = \rho_{t}(\theta, \gamma)^{-\gamma} \alpha \frac{Y_t}{K_t} - \frac{\phi}{2} \left( \delta^2 - \left( \frac{I_t}{K_t} \right)^2 \right) + (1 - \delta)Q^m_t
\]

with

\[
R_{t}^{km} = \frac{Q_t - Q_{t-1}}{Q_{t-1}}
\]

Then, \( Q^m_t \) replaces \( Q_t \) in the equations in Table 3, respectively defining the dynamics of firms’ net worth, banks’ net worth, and the subsequent external finance premiums. So, when \( Q^m_t > Q_t \), the firms’ and banks’ net values increase without any fundamental justification. The seeming improvement of their balance sheet allows them to obtain better conditions for external financing, stimulating the national investment and output (and inversely in case of adverse financial shock).

2.2 The model parameterization

The calibration for the parameters and the variables (or ratios) at their steady-state is detailed in appendix B, and is made according to the references found in the literature for the euro area. Ratios such as capital/GDP, investment/GDP or total consumption/GDP are all compatible with the estimations revealed by Fagan & Al. (2001). Moreover, it is realistically supposed that banks have a lower default probability than firms, and that the ratio \( \frac{NB}{B} \) belongs

---

10 Then, the financial shock corresponds to a one-period financial bubble, whereas Bernanke & Gertler (1999) and Levieuge (2009) simulate an exogenous multi-period one. The aim here is not to reproduce the effects of a long-lasting financial bubble, but simply to adequately insert financial shocks in the model.
to the interval \([0.1,0.2]\). Finally, the probability for a bank to leave the credit market is lower than for firms, and as already evoked, the audit is more costly for households than for banks. *Structural financial heterogeneity* is introduces among countries in the national banking system, at two levels: (i) in the ratio inside capital on loans for banks at the steady-state, and (ii) in the sensitivity coefficient of the banks’ external finance premium to their financial leverage. Country 1 is thus assumed to be more sensitive to shocks than country 2.

3. The role of common monetary policy to amplify national divergences

As in Badarau & Levieuge (2010b), the conduct of a single monetary policy for the (financially asymmetric) union as a whole worsens the cyclical divergences. *Figure 1* comparatively depicts the dynamics of countries 1 and 2 after a symmetric monetary shock, when they form a monetary union or not.

*Figure 1. Macroeconomic divergences with common vs national monetary policies*

---

11 See, for example, the numerical values used by Sunirand (2003) and Levieuge (2009) for the euro area.
We can observe that, in a monetary union, the output of the country 1 (stronger affected by the bank capital channel) is instantly 60% higher than in country 2. In contrast, if each country were supposed to conduct autonomously its monetary policy, the output response in the country 1 would be only 20% higher than in country 2. In other words, a common monetary policy in an asymmetric union implies a stabilization bias comparatively to national policies. Since a single monetary policy seeks to stabilize the average inflation in the whole area, country 2 will benefit from an even lower real interest rate than under a national monetary policy, while country 1 is affected by an even higher real interest rate than under a national policy. This real interest rate differential, which is favorable to the least sensitive country, explains the increased divergences inside the union. A single monetary policy that only reacts to average variables of an asymmetric union worsens the cyclical divergences among member countries.

In this respect, we wonder in the following section whether the consideration of national information for the conduct of monetary policy is likely to mitigate cyclical disparities, and whether national budgetary policies could represent useful tools to reduce divergences.

4. Macroeconomic policies to mitigate the effects of financial heterogeneity

This section aims to study the suitable macroeconomic policy-mix for a monetary union in a context of financial heterogeneity, as described by empirical evidence mentioned in the introduction, in a situation in which financial shocks are not insignificant.

On the one hand, we consider an independent common Central Bank, like the European Central Bank, whose policy is responsible for the union-wide price stability and which does not cooperate with the national governments (in accordance with the Article 130 of the Treaty). On the other hand, decentralized budgetary policies are conducted by the national governments. Alternative strategies for the Central Bank (centralized or based on national information) and for the governments (budgetary cooperation or autonomous conduct of national budgetary policies) are analyzed following a sequential game. The Central Bank chooses first its strategy. National governments define afterwards their policies.\footnote{This sequential solving is usual and logical in the euro area context. See Andersen (2005) for instance.} Simple monetary and budgetary rules are optimized and evaluated in terms of welfare gains, under each configuration.

As indicated in (12), the monetary policy rule links the short-term nominal interest rate to the union-wide inflation. Two configurations are alternatively considered for the optimization of $\beta_0$ and $\beta_1$. Firstly, in the centralized strategy, the Central Bank just stabilizes the average inflation for the union, and is not concerned by national divergences. The loss function to be minimized is:\footnote{Following Woodford (2003), the Central Bank loss function could be derived from the intertemporal utility}
\[ L^{BC} = \text{var}(\hat{x}^{UM}) + \lambda \text{var}(\Delta \hat{r}^n) \]  
(15)

where \( \text{var}(\hat{x}) \) defines the second order moment for the variable \( \hat{x} \), and \( \Delta \hat{r}^n = \hat{r}^n - \hat{r}^{n-1} \). \( \lambda \) is the relative importance given by the monetary policy to the interest rate smoothing.

Secondly, a monetary strategy based on national information responds to the situation in which the Central Bank is simultaneously concerned by the union-wide inflation stabilization and by the stabilization of the inflation differentials inside the union (see Badarau-Semenescu & al., 2009). The loss function of the Central Bank becomes:

\[ L^{BC} = \text{var}(\hat{x}^{UM}) + \lambda \text{var}(\Delta \hat{r}^n), \text{ for } \hat{r}^{UM} = \frac{\hat{r}_t - \hat{r}_t^*}{2} \]  
(16)

Governments’ decisions take the form of active budgetary rules (11) and (11’), whose coefficient \( \rho_y, \rho_y \) and \( \rho_i \) have to be optimally chosen so as to minimize the national loss functions. Two configurations are considered again. In the non-cooperative budgetary policy regime, which refers to an autonomous conduct of national policies, each government optimize a national loss function (17), considering as exogenous the public expenditures of the other country:\textsuperscript{14}

\[ L^G = \lambda^G \text{var}(\hat{x}) + \lambda^G \text{var}(\hat{y}) + \lambda^G \text{var}(\hat{g}) \]  
(17)

\( \lambda^G_x, \lambda^G_y \) and \( \lambda^G_g \) define the national preferences for inflation, output and public expenditures stabilization, respectively.

In the cooperative budgetary policy regime, both governments are endowed by a unique cooperative loss function, calculated as the average of the national loss functions:

\[ L^{\text{Coop}} = \frac{1}{2} (L^G + L^G^*) \]  
(18)

Note that, according to the new Treaty of Lisbon, entered into force on 1\textsuperscript{st} December 2009, national governments benefit from autonomy in the conduct of their budgetary policies. However, they are supposed to respect a global orientation for the budgetary policy defined at

the union-wide level. Such global orientation, which is still unclear in the treaty, is interpreted hereafter as a commitment of national governments to follow symmetric stabilization objectives for their budgetary policy. This implies in our model that \( \lambda^G, \lambda^G_y \) and \( \lambda^G_g \) in (17) are identical for the two countries. This institutional framework can be seen as an implicit coordination mechanism that covers not only the cooperative, but also the non-cooperative budgetary regime.

4.1 Some optimization results

First, we optimize the behavior of the common central bank. The context corresponds to the presence of both symmetric technological and financial shocks in the union, and the monetary decisions are supposed independent on the governments’ behavior. The optimal coefficient \( \beta_1 \) appears higher in the centralized strategy \((\beta_1 = 1.45704)\) compared to the national information based strategy\(^{15}\) \((\beta_1 = 1.43749)\). As expected, the centralized monetary policy is thus more reactive to symmetric shocks than a policy taking into account the specific situation of member countries.\(^{16}\)

Second, given the optimal policy of the central bank, governments’ optimize their behavior either in a non-cooperative or in a cooperative regime. Considering the centralized optimal monetary policy as given, the optimization of the budgetary rules is summarized in table 4 for the non-cooperative budgetary regime, and in table 5 for a cooperative budgetary regime, respectively.\(^{17}\) To verify the results robustness, different scenarios were defined each time for the governmental loss functions coefficients: \( \lambda^G, \lambda^G_y, \lambda^G_g \).

For the non-cooperative regime (table 4), the corresponding Cournot-Nash solutions clearly indicate that, whichever coefficients for the governmental loss functions, the coefficients for inflation and output stabilization are (as expected) negative in the budgetary rules. Moreover, taken in absolute value, these coefficients are systematically lower in country 2 than in country 1. Precisely, in the calibration, country 1 was supposed to be more sensitive to shocks. It thus needs more stabilization by the budgetary policy, and it is exactly what the government does. This means that, with a simple non-cooperative budgetary regime, national governments could play an active role in mitigating asymmetries in the transmission of shocks due to the structural heterogeneity of the union.

\(^{15}\) In line with Sauer & Sturm (2007), Fourçans & Vranceanu (2007) et Licheron (2009), \( \beta_0 \) is equal to 0.96.

\(^{16}\) For asymmetric shocks, the situation reverses. As in Badarau-Semenescu & al. (2009), they are better stabilized under a monetary policy who tries to reduce inflation divergences, than under a centralized monetary policy.

\(^{17}\) Results with an inflation-divergences oriented monetary policy are qualitatively similar (see tables in appendix C).
In contrast with these results, optimal cooperative budgetary rules are not consistent with the stabilization needs of member countries in Table 5. For example, the coefficient associated to the inflation gap in the budgetary rule of country 2 is positive, corresponding to a definitely destabilizing effect of the government optimal actions in this country.

At first glance this result seems counter-intuitive. But, following Badarau-Semenescu & al. (2009), it is easy to show that the cooperative loss function $L^{\text{Coop}}$ can be alternatively written:
\[ L^{\text{Coop}} = \lambda_x^G \text{var}(\pi^{UM}) + \lambda_y^G \text{var}(y^{UM}) + \lambda_r^G \text{var}(g^{UM}) + \lambda_x^G \text{var}(\hat{\pi}^{UM}) + \lambda_y^G \text{var}(\hat{y}^{UM}) + \lambda_r^G \text{var}(\hat{g}^{UM}) \] (19)

This function implicitly incorporates centralized stabilization objectives and national divergences stabilization objectives. Since all governments accept to fight divergences in the union, one possible solution is that each economy makes an effort to reach the average performance of the union. This explains the positive sign of the national inflation stabilization in the budgetary rule of country 2 (which is supposed to be less affected by shocks). Consequently, the cooperative budgetary regime is not necessarily suitable in an asymmetric monetary union. The need for responding to divergences in inflation, output and public expenditures finally makes the individual stabilizations less satisfying than in the non-cooperative regime.

Figure 2 illustrates this point, in case of restrictive and symmetric monetary shock. As the government in country 2 takes care of macroeconomic divergences in the union, its policy is not expansionist enough to duly stabilize its national output (otherwise it risks to exacerbate the divergences). Precisely, reaction to inflation divergences implies a reduction of public expenditures in country 2 simultaneously to an increase in country 1 (cf. \( \rho_x \) and \( \rho^*_x \) coefficients in table 5). Moreover, the reduction of output divergences implies a lower increase of public spending in country 2 relatively to country 1 (see \( \rho_y \) and \( \rho^*_y \) coefficients in table 5).

All in all, the cooperative regime allows a better stabilization of the divergences between the member countries, but national variables are then less stabilized than under a non-cooperative regime (the decline in output in particular is higher under a cooperative regime).

**Figure 2. National responses to a restrictive monetary shock**

(for \( \lambda_x = 1; \lambda_y = 1.5; \lambda_r = 0.5 \))
Certainly, the budgetary response of country 2 to government spending divergences asks for an increase of national expenditures, but this pressure is insufficient to compensate the reaction to inflation divergences. Consequently, as the global effect of these mixed forces finally leads to (excessively) moderate public expenditures (at the national level) in country 2, the country 1 in turn can not plan to implement an ambitious stimulus scheme. Otherwise, it would be penalized by a growing public expenditures gap. In other words, in country 1, the lower stabilization of the national variables is explained by the reaction of the budgetary policy to government spending divergences. This reduces the amount of public expenditures in the cooperative regime, compared to the non-cooperative one, with consequently less stabilizing effect on the economy.

</tbody>
</table>

*The numerical values in the table give the ratios between the standard deviation of the variable \( x \) (computed for the first 5 periods after the shock) in the cooperative regime compared to the non-cooperative one: \( \frac{\sigma_{Coop}^x}{\sigma_{NCooop}^x} \), for \( x \in \{ y_1, y_2, \pi_1, \pi_2, \bar{\gamma}^{UM}, \bar{\pi}^{UM} \} \).

All in all, the cooperative regime allows for a better stabilization of divergences in the union compared to the non-cooperative one, but, since it would be done to the detriment of the national variables stabilization, it is not really acceptable for member countries. Table 6 clearly depicts this fact, not only for the previous monetary shock, but also for a financial shock.

4.2 Policy-mix analysis

In this paragraph, we analyze the qualitative properties of four alternative policy-mixes (centralized / inflation-divergences oriented monetary policy with cooperative / non-cooperative budgetary policies), evaluated with respect to a union-wide social loss function, computed as the average of national social loss functions:

\[
EL_\gamma = \frac{1}{2} \left[ \lambda_\gamma \text{var} (\hat{y}) + \lambda_\gamma \text{var} (\hat{\pi}) + \lambda_\gamma \text{var} (\hat{\gamma}) + \lambda_\gamma \text{var} (\hat{\pi}) + \lambda_\gamma \text{var} (\hat{y}) + \lambda_\gamma \text{var} (\hat{\pi}) \right] \tag{20}
\]

\( \lambda_\gamma, \lambda_\pi, \lambda_\gamma \) are symmetric preferences for the stabilization of output gap, inflation and public expenditures in the national social loss functions.
Two cases are considered. On the one hand, it is assumed that governments share the same preferences as the society for inflation and output stabilization: \( \lambda^G_x = \lambda^G_y \) for \( x \in \{y, \pi\} \). On the other hand, since the national aggregates are not correctly stabilized under the cooperative regime (see table 6), we wonder what happens if the social stabilization preferences deviate from the governmental ones. We reasonably consider that the society is essentially concerned about inflation and output stabilization and less concerned about the public expenditures stabilization (see, in extremis, \( \lambda^G_g = 0 \)).

The evaluations for these different policy-mixes are reported in Table 7. Three sets of social loss function’s coefficients are considered and reported in the first column. The second column compares the expected losses issued from alternative budgetary regimes, independently of the monetary policy design. The third column compares the expected losses issued from alternative monetary strategies for the Central Bank, independently of the budgetary regime.

![Table 7. Expected social loss comparison for alternative policy-mixes](image)

\* \( EL_{S}^{C} \) = expected social loss with a centralized monetary policy; \( EL_{S}^{C+Div} \) = expected social loss with monetary policy based on national information; \( EL_{S}^{NCoop} \) = expected social loss in a non-cooperative budgetary regime; \( EL_{S}^{Coop} \) = expected social loss in a cooperative budgetary regime.

The last column clearly shows that, whichever the social and governments’ stabilization preferences, the expected loss of a centralized monetary policy is systematically lower than in the alternative case, where the Central Bank fights inflation divergences in the union. This
indicates that a change in the monetary policy design, in favour of inflation divergences, is not suitable\textsuperscript{18}. Concerning budgetary regimes, under the assumption of identical social and governmental stabilizing preferences in the union, the results favour the cooperative regime over the non-cooperative one. But the relative benefit of the cooperative regime comes only from the stabilization of public expenditures and the decrease of their divergences inside the union ($\lambda^c_s \neq 0$). Indeed, the computation of the alternative social loss function solely defined in terms of inflation and output stabilization ($\lambda^c_s = 0$) reasserts the superiority of the non-cooperative regime with implicit coordination mechanism\textsuperscript{19}, as indicated in figure 2.

5 Conclusions

Considering the well-documented financial heterogeneity of the euro area, paying attention to the bank capital channel (which has generated great interest for several years), and to financial shocks (which are now recurrent), this paper aims to study the suitable policy-mix in such a context. The analysis relies on a dynamic stochastic general equilibrium model, calibrated in reference to previous studies for the euro area. This model generates conventional dynamics, and particularly shows that the conduct of a single monetary policy for an asymmetric union as a whole seriously worsens national divergences.

The normative conclusions are the following. Firstly, it appears that a centralized monetary policy dominates a strategy based on inflation divergences in the Union, whatever the budgetary regime. This conclusion confirms previous results in the literature, according to which the aversion of the common Central Bank to national divergences could be beneficial only if it focuses simultaneously on inflation and output (what is not the case for the ECB). Secondly, decentralized budgetary policies need to be more proactive in countries that are structurally more sensitive to shocks (those where the bank capital channel is stronger). In that case, budgetary policies can contribute to mitigate the effects of adverse shocks. Thirdly, a cooperative budgetary regime (defined as the average of the national objective functions) can be counterproductive. Indeed, each country has then to make a step toward a common target (partly defined as a combination of inflation, output and public spending divergences, besides their own national

\textsuperscript{18} As discussed in Badarau-Semenescu & al. (2009) such modification would be beneficial only if it is supported by simultaneous consideration of output divergences in the union.

\textsuperscript{19} So, the case in which $\lambda^c_s = 0$ is useful to demonstrate that the superiority of the cooperative regime is mainly due to a better stabilization of public spending divergences.
targets) in order to respect the objective of macroeconomic convergence this regime implicitly implies. If structural heterogeneity is important, this returns to be unsatisfactory for any country: national variables are less duly stabilized than under a non-cooperative regime (notwithstanding with an implicit coordination mechanism implying similar objective functions in the member countries, what is an interpretation of the global common orientation promoted by the new Treaty of Lisbon). Finally, the cooperative regime is preferable only because it allows a better stabilization of public spending divergences.

Typically, in the context of diverging responses by European economies following the subprime mortgage crisis, a cooperative budgetary regime would have implied an insufficient reaction of national governments, with regards to what their own situation had required. Caring about inflation divergences between the members, the less affected countries like France for instance would have had to refrain from ambitious stimulus plan (compared to what should be nationally required). Otherwise, they would have been responsible for worsening macroeconomic divergences, what is inconsistent with “cooperation”. In the same way, the most affected countries, like Italy for example, would have been constrained to circumscribe their economic stimulus plan, in order to limit the public spending divergences. All in all, European countries would not have benefited from a cooperative budgetary regime, whatever their sensitivity to the financial shock.
